To eliminate the chromatic aberration, a prism may be used at the imaging plane to produce spherical instead of planar light. This is called a spherical illumination. When a simple converging lens with this configuration is used, a converging beam of light forms an image of the object at its focal point. However, since the focal length is only an estimate, the spherical light will be focused at a point in front of the true focal plane. Also, since the light is diverging, at a distance from the focal point the image is diverging too. This is called spherical aberration. To prevent these phenomena, a double converging lens, in addition to a spherical illumination, is used to form an image of the object at the focal plane. When a double converging lens is used, the inner lens, which produces the converging beam, acts as a simple converging lens, like that used for a single converging lens. The outer lens, which is usually called a correcting lens, acts as a prism. This corrects the chromatic aberration by focusing the converging beam at the correct focal plane. When the focal length of the outer lens is less than the distance between the two focal points, the converging beam is thinner in the middle, causing a height distortion in the image. However, if the object distance is sufficiently far from the focal plane, the thin rays in the middle converge on the image plane at the same distance behind the focal plane as the thicker rays on either side of the thin center ray. This produces paraxial focus.

in the defocus process, the cornea, which is not fixed, distorts the shape of the light rays causing them to be focused on the retina. therefore, the image is inverted (upside-down, figure 14.6), and reversed (right-left, figure 14.7). if the viewed object is brought closer to the eye, the light rays from the object diverge at a greater angle relative to the eye (figure 14. the class is used to create regions of dynamic geometry. you define the geometry by creating a path of the appropriate geometric elements. the geometry of a region can be defined by creating a collection of line, polyline, circle, ellipse, rectangle, star, polygon, polyline, path, or polygon geometry objects. nanite has a massive internal memory compression algorithm that uses complex mathematical equations to optimize for runtime inefficiencies. this algorithm can handle the complex math needed to find the optimal points on the triangle for the smallest triangles with no need for more than one pass of the triangles. nanite's streaming can handle any number of triangles or objects and can be used as an efficient preprocessor to other rendering engines. a object is used to assign vertex attributes to more than one vertex of a mesh. the attributes are associated with the vertices in the order in which they are listed in the mesh. all vertices sharing the same attributes receive the same values. a can be used to assign vertex data to multiple vertices in a single mesh. for example, you can assign vertex data to the vertices of an mesh, or you can assign vertex data to one or more vertices of a mesh. 5ec8ef588b
